

# falling chain

(submitted by Ilkka Mäkinen)

A chain of length  $L$  cm and mass  $M$  kg is suspended vertically by one end with the other end immediately above a scale. The chain is released and falls. At the instant the entire chain has fallen onto the scale what does the scale read?

## Solution by Sukumar Chandra:

As the chain is falling freely under gravity so at any instant  $t$  after the chain is released, when its free end goes down by  $x$ , the speed  $v$  of the chain is given as  $v = \sqrt{2gx}$ .

In further small interval of time  $\Delta t$ , a small length of chain  $\Delta x$  of mass  $(\Delta x M) / L$  strikes the scale with a speed  $v$  and comes to rest. This results in a loss of momentum of the chain of magnitude  $(\Delta x M v) / L$ . As this loss takes place in time  $\Delta t$ , so the rate of loss of momentum of the chain is  $(\Delta x M v) / (L \Delta t)$ . Thus the scale exerts an upward force of  $(\Delta x M v) / (L \Delta t)$  or  $M v^2 / L$  (as  $\Delta x / \Delta t = v$ ) on the chain which means the chain also exerts equal and opposite force on scale. Also at this instant the  $x$  length of the chain exerts its own weight too,  $M g x / L$  on the scale. Hence the total force the chain exerts on scale when it comes down a length  $x$  is  $(M v^2 / L + M g x / L)$  or  $3 M g x / L$  as  $v = \sqrt{2 g x}$ . In other words when the chain falls by a length  $x$ , the scale reads  $3 M x / L$ .

So when the chain has fallen a length  $L$ , the scale reads  $3 M$ .
